Purpose: Problems associated with a complete denture, such as lack of stability and retention, can be solved with the use of implant-retained or implant-supported overdentures. However, controversy exists as to the anchorage system used and indications for both the maxilla and mandible. The purpose of this review was to identify the prosthetic complications associated with the different attachment mechanisms used for implant-supported or implant-retained overdentures. Materials and Methods: A search of the MEDLINE and PubMed databases was conducted to find articles in English and German peer-reviewed journals published between 1980 and 2008. The search focused on randomized controlled clinical trials and prospective studies with follow-up periods of at least 5 years that contained clinical data regarding success, failure, and prosthetic complications. Results: The search yielded a limited number of randomized controlled clinical trials referring to implant-supported or implant-retained overdentures. Very few studies have prospectively compared prosthetic complications for a period longer than 5 years after delivery of the prosthesis. Conclusions: Implant-supported or implant-retained overdentures in the mandible provide predictable results with improved stability, retention, and patient satisfaction. Scientific evidence shows a lower rate of implant survival and a higher frequency of prosthetic complications for maxillary implant-retained or implant-supported overdentures. Although the literature presents considerable information on complications of implant prostheses, variations in study design preclude proper analysis of certain complications. Well-designed longitudinal studies are required to establish evidence-based treatment planning principles. Int J Prosthodont 2010;23:195–203.

Edentulous patients with a severely resorbed mandible or maxilla often experience problems with conventional dentures, such as insufficient stability and retention, together with a decrease in chewing ability.1,2 Because of the good prognosis of dental implants, these patients can be successfully treated with implant-retained or implant-supported overdentures.3 Several studies reported the following benefits of overdenture in comparison to complete denture treatment in the mandible: better chewing ability, better fit and retention, improved function, and improved quality of life.4 Controversially, very few studies have evaluated patient satisfaction with maxillary overdentures. Data show that there is no significant improvement of the above parameters for overdenture wearers when good bony support exists for the fabrication of maxillary conventional prostheses.5,6 However, since many patients have problems with the retention of their mandibular prosthesis and do not desire implant-supported fixed prostheses, mainly because of financial reasons, the removable implant-retained or implant-supported overdenture has become a reliable treatment alternative, offering the same masticatory efficacy as a fixed prosthesis.6,7
The purpose of this review was to provide information on the types of prosthodontic complications associated with implant-retained or implant-supported overdentures.

Materials and Methods

Search Strategy

A broad search of the dental literature in MEDLINE and PubMed was performed for articles published between 1980 and 2008. A focus was made on peer-reviewed dental journals limited to studies in English or German conducted with human subjects and using both medical subject headings (MeSH) as well as keywords. The last electronic search was conducted on November 31, 2008. The search strategy included the combination of the following MeSH terms: “dental implants” + “dental prosthesis, implant-supported,” “dental implants” + “complications,” “dental prosthesis, implant-supported” + “complications,” “dental implants” + “complications” + “dental prosthesis, implant-supported,” and the keywords: “implant overdentures,” “technical complications,” “mechanical complications,” “screw-retained,” “screw mechanics,” “prosthesis screw loosening,” “abutment screw loosening,” “prosthesis screw fracture,” “abutment screw fracture,” “metal framework fracture,” “acrylic veneer fracture,” and “maintenance.”

Manual searches of the references of all full-text articles and relevant review articles selected from the electronic search were also performed.

Selection Criteria

To determine which studies to include in the present systematic review, the following additional inclusion criteria were applied (Table 1): clinical studies reporting on prosthodontic complications with removable implant-supported or implant-retained overdentures, RCTs and prospective studies with a mean follow-up period of ≥5 years, number of subjects and implants stated, and clear outcome stated (implant survival/success rate and prosthodontic complications reported). Standard reviews, in vitro studies, case reports, and experience reports and retrospective clinical studies were excluded because of possible study selection bias and limited clinical relevance, respectively.

Review Methods

The titles and abstracts, when available, of all reports identified through the electronic searches were assessed independently by two reviewers. For studies appearing to meet the inclusion criteria, or for which insufficient data were available in the title and abstract.
to make a clear decision, the full-text version was obtained. The full-text reports of all studies of possible relevance were once again assessed independently by the two reviewers to establish whether they met the inclusion criteria. Manual searches of the references of all full-text articles and related reviews were also performed, and the potentially relevant papers were scrutinized. Any disagreement between the reviewers regarding selection of the studies was resolved by consensus. All studies meeting the inclusion criteria underwent validity assessment and data extraction. All publications found were entered into a reference database (EndNote, version 11, Thomson ResearchSoft).

Quality Assessment and Data Extraction

The quality assessment of the included trials was undertaken independently and in duplicate by two reviewers as part of the data extraction process. The publications were sorted into prospective studies and RCTs. They were assessed for allocation concealment, blindness of outcome assessment, definition of inclusion and exclusion criteria, adjustment for potential confounding variables, and completeness of follow-up and statistical analysis. Any disagreement regarding data extraction was resolved with discussion. Data were excluded if an agreement could not be reached. For each trial, the following data were recorded: study design, first author, year of publication, observation period, number of subjects and implants, number of subjects and implants followed for ≥ 5 years, success/survival rate of the implants, and type of prosthesis.

Results

The initial electronic search generated 2,631 articles. After applying additional inclusion and exclusion criteria and screening the titles and abstracts, the review process included 117 articles. The extensive examination resulted in a final sample of 18 studies that were considered for further evaluation, namely 4 RCTs and 14 prospective clinical trials with follow-up periods of at least 5 years. Additionally, systematic reviews, classical articles, and retrospective studies were referred to in the present review, with the consideration that these sources do not have the same weight of evidence. Meta-analytic methodology was not applied in the current systematic review because of the variation in the types of experimental characteristics of the investigations. This decision was based on the premise that meta-analysis can only be performed when the studies share sufficient similarity to justify a comparative analysis. Figure 1 describes the process of identifying the 18 articles selected from an initial yield of 2,631 titles.

Acknowledging the obvious limitations for strong evidence in this field, an attempt was made to assess the available literature concerning commonly discussed issues related to implant-retained or implant-supported overdentures, as well as prosthetic complications.

Implant Survival/Success and Type of Attachment

The current literature search revealed only 14 prospective studies and 4 RCTs addressing the prosthetic complications and implant survival/success rates of patients treated with implant-supported or implant-retained overdentures after a period of at least 5 years (Table 2).

Information regarding implant-supported or implant-retained overdentures in the maxilla was found in only four studies, none of which were RCTs. Maxillary overdentures generally involved an implant-splinted bar on a maximum of four to six implants. The implant success rate ranged between 72.4% and 84%. The study of Attard and Zarb reported a cumulative survival rate of 96% and a cumulative success rate of 93%. According to the systematic review of Bryant et al., the pooled implant survival estimate was 76.6% at 5 years. Data regarding survival rates of implants after observation periods of more than 10 years were in short supply.

As for the outcomes of mandibular implant-supported or implant-retained overdentures, it seems that there is more evidence available than that with maxillary overdentures. Of the 17 studies identified, only 4 were RCTs and 4 of the prospective studies had an observation period of at least 10 years. The majority of studies employed bars, balls, or magnets as attachment systems. Only one additional study evaluated soft and hard tissue conditions as well as the function of telescopic copings for implant overdentures. In most studies,
overdentures were supported by two implants, but there were also studies with one, three, four, or more implants. Implant survival did not appear to vary by splinting, rotational characteristics, or the number of implants and ranged from 93% to 100% at 10 years. Bryant et al showed that the pooled implant survival rate in the mandible after 10 years was 95.4%. The statistical finding that implant survival in the mandible exceeds the outcomes in the maxilla reinforces the long-established evidence of a somewhat elevated vulnerability of the edentulous maxilla for implant failure. Although no clear evidence is available, several studies demonstrated that failures in the maxilla are related to short implants, poor bone quality or quantity, and a small number of implants. However, the recent development in the field of new implant surfaces could lead to higher integration rates in the maxilla.

**Definition of Clinical Complications**

There are two categories of complications that occur in implant therapy: biologic and technical (mechanical). The present review focused on the technical complications that were related to implant-supported or implant-retained overdentures. "Technical complications" served as a collective term for mechanical damage to the implant and implant components and superstructures. Such complications included implant fracture, wear or corrosion of the retention elements, fracture of the retention elements or superstructure, abutment fracture, abutment screw loosening or fracture, attachment screw loosening or fracture, activation or changing of the clip, matrix activation (change of rubber ring) or replacement (change of O-ring housing), changing of the magnet, rebasing or relining of the overdenture, and overdenture fracture.
Prosthetic Success and Incidence of Technical Complications

In contrast to implant survival/success rates, the percentage of prosthetic survival/success ranged widely between the studies and prosthetic types and was generally not calculated cumulatively. The data obtained showed that prosthetic maintenance is inconsistent between different studies. Variable definitions of events, visits, and occasions were used with or without accounting for prosthetic maintenance conducted at routine reassessment visits. Bryant et al.\(^{32}\) could not calculate an overall complication incidence for implant overdentures because there were no multiple clinical studies with a similar study design that simultaneously evaluated all or most of the categories of complications. On the other hand, Berglundh et al.\(^{36}\) in a systematic review, observed that a 4- to 10-times higher incidence of prosthetic complications was associated with implant-supported or implant-retained overdentures in comparison to implant fixed prostheses.\(^{36}\)

Goodacre et al.\(^{35}\) combined raw data from multiple studies and calculated means in an attempt to identify trends noted in the incidence of complications. For a specific complication to be included, three or more studies must have reported data related to the incidence of that particular complication. The authors clarified that the mean percentages presented in their study suggested trends rather than absolute incidence values and should be interpreted cautiously due to the large variation in numbers of implants and prostheses evaluated and the lack of statistical analysis. The following complications were reported (listed in order of frequency): overdenture loss of retention or adjustment (30%), overdenture rebasing or relining (19%), clip or attachment fracture (17%), overdenture fracture (12%), opposing prosthesis fracture (12%), acrylic resin base fracture (7%), prosthesis screw loosening (7%), abutment screw loosening (4%), abutment screw fracture (2%), and implant fracture (1%).\(^{35}\)

Irrespective of the anchorage system used, adjustments to the overdenture attachment system were the most common mechanical problem in implant prosthodontics.\(^{11,21,24-29}\) In an RCT, Naert et al.\(^{13}\) compared the prosthetic aspects of three different attachment types (ball, bar, and magnets) in two implant-retained mandibular overdentures. In the ball group, renewal of the O-ring housing and rubber ring and abutment screw loosening were the most common mechanical complications after an observation period of 10 years. In the magnet and bar groups, the most frequent complications were wear and corrosion and the need for clip activation, respectively.\(^{13}\) Compared to the bar group, the magnet and ball groups presented the highest incidence of prosthetic complications.\(^{11,26}\)

Conversely, significantly more complications and repairs were reported in the bar group compared to the ball group during the first year of function. However, no significant differences between the different attachment systems were observed in the following years.\(^{12}\) Another point of concern is the distinction between resilient (Dolder) and rigid (milled) bars regarding their prosthodontic maintenance. In contrast to well-established clinical use and the numerous publications regarding hinged overdentures, very few data exist comparing the use of resilient or rigid bar stabilization. In a recent study, Krennmaier et al.\(^{30}\) reported that when four interfurcal implants were used to anchor mandibular overdentures, the design of the anchorage system significantly influenced the need for prosthodontic aftercare. Rigid anchorage using milled bars and a metal-reinforced denture framework required less prosthodontic maintenance than resilient denture stabilization with multiple round bars and dentures without frameworks. Similarly, Dedic and Merieske-Stern\(^{17}\) found a significant superiority of the mandibular rigid bar design versus the resilient bar configuration after 2 and 5 years of follow-up but not after a period of 15 years. A change from a resilient retention device to a rigid bar was performed more often than vice versa, but not at a statistically significant level.

Concerning the telescopic crowns as an anchorage system for implant overdentures, there are very limited long-term data in the literature. In the only longitudinal prospective study included, Heckmann et al.\(^{14}\) investigated the clinical function of nonrigid telescopic crowns over an observation period of 10 years. Out of a total of 46 telescopic crowns (16 cemented and 30 screw-retained), 4 primary copings had to be recemented during the follow-up period (25%), while loosening of the occlusal screw occurred in 5 implants (16.6%). Relining of the overdentures occurred with an incidence of 21.7%.\(^{14}\)

In general, a higher incidence of mechanical problems was reported with implant-supported or implant-retained overdentures in the maxilla compared to those in the mandible, especially for maxillary overdentures without palatal coverage. Limitations in vertical space for the prosthetic components and matrix were more common in the maxilla, which resulted in compromises in design and material failure. After a 5-year follow-up, Watson et al.\(^{25}\) reported a threefold increase in fractures of overdentures in the maxilla compared to those in the mandible. However, a cast chromium-cobalt framework reinforcement was reported to eliminate this complication. Regardless of the anchorage system, the predominant complication in maxillary overdenture therapy involved a change in the retention system resulting from loosening or fracture of the prosthetic components.\(^{37}\)
Discussion

In the present review, a number of longitudinal cohort studies were analyzed with respect to prosthodontic complications related to implant-retained or implant-supported overdentures. The main approach in the search was to identify studies of prospective design with follow-up periods of at least 5 years. Although the gold standard for systematic reviews is to study RCTs, which have the most robust design, most of the studies included in this review were prospective clinical trials. A retrospective study design and duration of < 5 years were the main reasons for exclusion.

Several retention systems for implant overdentures have been described in the literature. Differences between studies in regards to methods and lack of standardization of prosthetic procedures, as well as insufficient sample size, have prevented an objective assessment of the preferred retention system for implant-retained or implant-supported overdentures. The choice of a specific system seems to be based more on the clinician’s preference than on scientific evidence. Several clinical longitudinal studies have shown that there are no differences in implant survival and peri-implant variables between bar and unsplinted retention systems.15,16,26,27,38

Comparison of the Four Anchorage Systems

Although there is no significant difference in patient satisfaction with overdenture stabilization between the different attachments (both implant-supported and implant-retained), differences have been described regarding prosthetic maintenance during the follow-up period (Table 3).11,25,32,39,40

For selection of the appropriate type of attachments, the oral status, the financial situation of the patient, cost-effectiveness, and the patient’s expectations of the new overdentures must be considered.41 The anatomic situation in the mandible or maxilla is a critical factor. Advanced atrophy of the alveolar crest calls for prosthetic stabilization, especially with regard to horizontal forces, which can be achieved predominantly with bars and telescopic crowns.14,42 As a result of the presenting anatomy of the mandible or because the implants are placed in excessively distal locations, the tongue space may be restricted when using bars.39,43

More common limitations in the maxilla are in vertical space for the prosthetic components and matrix due to contour and phonetic considerations.27 In the vertical axis, a minimum distance of 13 to 14 mm from the implant platform to the incisal edge of the overdenture is necessary for the bar attachment, allowing 4 mm for the bar and 1 mm between the bar and gingiva for hygiene, as well as space for the clip and the acrylic/tooth housing.44 Solitary anchors require only 10 to 11 mm of vertical space above the implant platform and therefore offer more flexibility.

It also has been demonstrated that solitary attachments are less costly and less technique sensitive, while clinical experience shows that secondarily blocked constructions ease oral hygiene procedures considerably for elderly patients compared with bars.37,45,46 In a comparative study, the bar group revealed more mucositis and gingival hyperplasia, whereas the solitary attachment group displayed more decubitus ulcers.16 Several longitudinal prospective studies have shown that there is no significant difference in the implant survival rate and marginal bone loss between subjects with overdentures retained with splinted or unsplinted anchorage systems.12,16,26,32

van Kampen et al demonstrated that bars provide more retention than solitary anchors when subjected to both vertical and oblique forces. Implant angulation may compromise the retention of solitary anchors. However, Chung et al showed that in cases of parallel-placed implants, solitary attachments such as Locators may match or exceed the Hader bar and metal clip retention. Naert et al demonstrated that the ball group presented the highest vertical retention capacity of the implant-retained overdenture and a remarkable increase in this retention capacity over time, whereas a decrease occurred in the magnet and bar groups. Magnets have been shown to be the least retentive of all attachment systems but may be appropriate for patients with bruxism or dexterity problems.10

Finally, the extent of prosthetic maintenance using different attachment systems should be considered. When

1 = least effective; 3 = most effective.
comparing bars with single anchors, controversy exists as to whether the bar or ball design requires more maintenance.\textsuperscript{12,26,49} Several studies have shown that there is no correlation between attachments and prosthetic complications, except for bars with distal extensions, which were more prone to fracture.\textsuperscript{17,26,50} It has also been shown that rigid bars retaining overdentures on four implants demonstrate a significantly lower incidence rate of prostodontic maintenance than a resilient anchorage system with round bars.\textsuperscript{30} In the study by Dudic and Mericske-Stern,\textsuperscript{17} fracture of bars or extensions and retightening of female parts was higher in the rigid group, whereas broken, loose, or lost retainers required significantly more repairs in the resilient group. Other studies demonstrated an increased amount of prosthetic maintenance for ball attachments and magnets because of wear or fracture of the ball head or need for activation of the ball matrix and corrosion or wear of the magnets.\textsuperscript{11,40,43,47} In terms of maintenance, the bar and the Locator attachment systems have been recommended when restoring implants with a divergence between 10 and 40 degrees.\textsuperscript{51} However, clinical studies comparing prosthetic maintenance of Locators with other attachment systems are in short supply.

**Etiology of Technical Complications**

To minimize potential problems during and after the restorative phase, attention must be paid to various factors that can lead to mechanical complications. A common problem associated with the prosthetic restoration of dental implants is loosening or fracturing of the attachment screws. This complication occurs mainly because of the magnitude and direction of the oral forces and the strength limitations of the components.\textsuperscript{52,55} Other factors such as operator error, torsion relaxation, and thermal changes may also contribute to screw loosening.\textsuperscript{53} Moreover, the amount of ridge resorption, the length and number of implants, the opposing dentition, the angulation of the implants, and parafunctional habits may increase the susceptibility for such complications.\textsuperscript{54} In the severely resorbed mandible, implants supporting or retaining an overdenture may be subjected to excessive masticatory forces by the mesial and distal cantilever and also from the occlusogingival lever arm. These forces include off-axis centric contacts, excursive contacts, cantilevered loading, and internal stresses created by both component and framework misfit.\textsuperscript{52} In the case of angulated implants, the occlusal forces may generate more strain than the screw can bear.\textsuperscript{52,55}

In addition to implant fracture, prosthesis fracture or acrylic resin failure or wear may occur. Such complications are observed when the applied loads exceed the material’s proportional limit or fracture strength.\textsuperscript{56} Other technical failures, such as material contamination, casting porosities, and poor alloy surface preparation, may also lead to prosthetic complications.\textsuperscript{54}

Misfit of the framework has also been suggested as an important factor as far as prosthetic failures are concerned.\textsuperscript{57} It should be considered that an absolute passive fit of a framework is almost impossible. However, studies designed to assess the effects of the degree of misfit of an implant-supported or implant-retained restoration on the implant bone-phase boundary have been unable to demonstrate a negative effect of misfit on this area.\textsuperscript{54}

Within the limits of this review, treatment recommendations have been posited given the available evidence. Therefore, cantilever lengths should be minimized, nonworking contacts should be eliminated, centric occlusion contacts should be centralized, and components should be torqued in accordance with manufacturer recommendations.\textsuperscript{58–60} Much effort should be taken to improve the fit of the prostheses.\textsuperscript{57}

As the etiologies of many technical complications are not fully clear, the clinician is left to weigh the costs and complexity of treatment. According to the principles of evidence-based dentistry, it is agreed that an RCT is the most scientifically sound method to establish reliable conclusions regarding the effectiveness of therapeutic alternatives.\textsuperscript{61} The proportion of RCTs in the prostodontic literature is, however, very small and further research is needed to provide better answers to the “how” and “why” of successful implant-supported or implant-retained restorations.\textsuperscript{62} The effects of design variables such as anchorage system used, maintenance, costs, patient satisfaction, and success of the reconstruction require better quantification and documentation so that basic guidelines can be established.

**Conclusions**

There is scientific evidence that a lower rate of implant survival and a higher frequency of prosthetic complications exist for maxillary implant-retained or implant-supported overdentures. The heterogeneity of studies dealing with prosthetic aftercare and maintenance does not allow an estimation of an overall complication rate. Further well-designed RCTs are required to establish evidence-based treatment planning principles for implant overdenture patients.

Elemental ion release from four different fixed prosthodontic materials

Many different alloys are used in fixed prosthodontics and it is important to know if elemental ions are released into the oral cavity when these prostheses are in use. The aim of this study was to investigate the release of metal ions from commonly used fixed prosthodontic materials and to quantify them. The alloys investigated were Type IV gold, nickel-chromium alloy, stainless steel alloy, and machinable ceramic. After fabrication, samples were immersed in 0.9% sodium chloride and 1% lactic acid solutions at 37°C for 7 days. The sodium chloride solution was used to simulate the pH of fresh, neutral saliva and the lactic acid simulated the pH of extremely acidic conditions. The elemental release was determined and quantified by using an inductively coupled plasma mass spectrometer. In both the sodium chloride and lactic acid solutions, Pd, Ag, Zn, and Cu were released from the gold alloy; Ni, Cr, Mo, Al, and Be were released from the nickel-chromium alloy; Ni, Cr, and Fe were released from the stainless steel alloy; and Al and K from the computer-aided design/computer-assisted manufactured machinable ceramic. In the lactic acid solution, the release of all elements was increased with the exception of Ag. These results suggest that a transient exposure of these prosthetic alloys to an acidic environment is likely to result in elemental ion release. Further studies need to be conducted to investigate if the amount of elemental ions released reported in this study pose an allergic or toxic risk to the patient.
